Niemann-Pick type C (NPC) disease results from mutations that inactivate 1 of 2 proteins, either NPC1 (95% of cases) or NPC2 (1, 2). These 2 proteins normally act in concert to facilitate the movement of unesterified cholesterol (C) from the endosomal/lysosomal (E/L) compartment to the cytosolic compartment of cells throughout the body. This defect results in activation of macrophages in many tissues, progressive liver disease, and neurodegeneration. In thenpc1<sup>−/−</sup> mouse, a model of this disease, the whole-animal C pool expands from 2,082 to 4,925 mg/kg body weight (bw) and the hepatic C pool increases from 132 to 1,485 mg/kg bw between birth and 49 days of age. A single dose of 2-hydroxypropyl-β-cyclodextrin (CYCLO) administered at 7 days of age immediately caused this sequestered C to flow from the lysosomes to the cytosolic pool in many organs, resulting in a marked increase in cholesteryl esters, suppression of C but not fatty acid synthesis, down-regulation of genes controlled by sterol regulatory element 2, and up-regulation of many liver X receptor target genes. There was also decreased expression of proinflammatory proteins in the liver and brain. In the liver, where the rate of C sequestration equaled 79 mg d<sup>−1</sup>kg<sup>−1</sup>, treatment with CYCLO within 24 h increased C movement out of the E/L compartment from near 0 to 233 mg d<sup>−1</sup>kg<sup>−1</sup>. By 49 days of age, this single injection of CYCLO resulted in a reduction in whole-body C burden of >900 mg/kg, marked improvement in liver function tests, much less neurodegeneration, and, ultimately, significant prolongation of life. These findings suggest that CYCLO acutely reverses the lysosomal transport defect seen in NPC disease.

Niemann-Pick type C (NPC) disease results from mutations involving the cellular uptake of lipoproteins, which normally aids movement of unesterified cholesterol (C) from the endosomal/lysosomal (E/L) compartment to the cytosolic compartment of cells throughout the body. This defect results in activation of macrophages in many tissues, progressive liver disease, and neurodegeneration. In each organ is internalized through 2 different transport mechanisms involving the cellular uptake of lipoproteins through either receptor-mediated or bulk-phase endocytosis. Receptor-mediated uptake utilizes the low-density lipoprotein receptor (LDLR) that is able to bind lipoproteins containing either apolipoprotein (apo) E or apoB<sub>48</sub>, such as remnants of chylomicrons and very low-density lipoprotein (VLDL), and LDL (11, 12). The velocity of this uptake process in a particular organ in vivo is determined by the concentration of lipoproteins in the plasma, the level of LDLR expression, the affinity constant for a given lipoprotein, and the reflection coefficient defining the permeability characteristics of the capillary membranes overlying the parenchymal cells of that tissue. The rate of uptake of lipoproteins by bulk-phase endocytosis is also determined by the concentration of the particles in the plasma and the reflection coefficient of the capillary membranes; however, in addition, it may be influenced by nonsolvent water effects within the endocytic vesicles (13). In thenpc1<sup>−/−</sup> mouse, 88% of LDL cleared from the plasma and sequestered in different tissues is taken up by receptor-mediated endocytosis, whereas only 12% is cleared by bulk-phase endocytosis (7). However, when LDLR activity is eliminated, as in thenpc1<sup>−/−</sup>ldlr<sup>−/−</sup> animal, all LDL is cleared by bulk-phase endocytosis. Because the rate constants for these two processes are very different in different organs, the profile of C sequestration in tissues varies markedly in thenpc1<sup>−/−</sup>ldlr<sup>−/−</sup> andnpc1<sup>−/−</sup>ldlr<sup>−/−</sup> animals (3). Importantly, these rate constants for lipoprotein uptake by either receptor-mediated or bulk-phase endocytosis are unaffected by the presence or absence of the NPC1 mutation. Whole-animal LDL clearance by receptor-mediated (∼520 mL·d<sup>−1</sup>·kg<sup>−1</sup>) and bulk-phase (∼62 mL·d<sup>−1</sup>·kg<sup>−1</sup>) endocytosis is approximately the same innpc1<sup>−/−</sup> andnpc1<sup>−/−</sup> mice (7). However, there is evidence that the lipid accumulation seen innpc1<sup>−/−</sup> cells does lead to a 2-fold expansion of the bulk-phase volume found within the lysosomal compartment and to a diminished rate of movement of this bulk-phase fluid back out of the cell (14).

One way to take advantage of these observations to control the severity of disease caused by the NPC1 mutation is to reduce the amount of lipoprotein cholesterol available for uptake into cells. Thus, blocking the intestinal absorption of sterol with a drug like ezetimibe, which lowers the amount of C reaching the liver carried in chylomycin remnants, markedly reduces hepatocyte damage and improves hepatic function (9). Increasing sterol excretion out of the brain across the blood-brain barrier, which presumably leaves less apoE-associated C available for uptake by neurons, slows neurodegeneration and prolongs the life of thenpc1<sup>−/−</sup> mouse (10).

liver function tests (9) but had no effect on longevity. However, the addition of Allo to either the CYCLO 4.5 or CYCLO 5.6 did not significantly further prolong life (number indicated for each group). In each experiment, the untreated control animals were littermates of the treated group.

An alternative approach to this problem would be to deliver an agent through bulk-phase endocytosis into cells that reverses the transport defect in the late E/L compartment, and allows the sequestered C to move into the metabolically active pool, where it could be metabolized and secreted through normal mechanisms. That such a manipulation might be possible is suggested by the observation that administration of the sterol-binding agent, 2-hydroxypropyl-β-cyclodextrin (CYCLO), also slows nerve cell death and prolongs the life of the npc1−/− mouse (15, 16). Thus, the current studies were designed to investigate the molecular and biochemical effects of the acute administration of CYCLO on sterol metabolism in the neonatal mouse and, further, to examine the more prolonged alterations that this single dose of CYCLO has on the natural history of NPC disease when the animal reaches maturity. The results suggest that this compound acutely and completely overcomes the transport defect caused by the NPC1 mutation.

Results

Effect of CYCLO on Age at Death. Untreated npc1−/− mice died at an average age of 84 days (Fig. 1A). Treatment of these mice from birth with ezetimibe (20 mg d−1kg−1), which blocks cholesterol absorption, markedly reduced C flux into the liver and greatly improved liver function tests (9) (Fig. 1B). A single dose of CYCLO 4.5 or 5.6 administered at 7 days of age did, however, significantly and equally prolong life. (See Fig. 1C. Addition of Allo to either the CYCLO 4.5 or CYCLO 5.6 did not significantly further prolong life (number indicated for each group). In each experiment, the untreated control animals were littermates of the treated group.

![Figure 1](https://example.com/figure1.png)

**Fig. 1.** Cyclo expands lifespan in the npc1−/− mouse. (A) Npc1−/− mice continuously fed ezetimibe, which markedly lowers cholesterol flux into the liver and improves liver function, did not live longer than those animals not fed this compound. (B) A single dose of CYCLO 4.5 or 5.6 administered at 7 days of age did, however, significantly and equally prolong life. (C) Addition of Allo to either the CYCLO 4.5 or CYCLO 5.6 did not significantly further prolong life (number indicated for each group). In each experiment, the untreated control animals were littermates of the treated group.

From the weights of the individual organs and whole animals (Fig. 2G), these values were used to determine the effects of the NPC1 mutation and treatment with CYCLO on whole-animal sterol metabolism in these 8-day-old mice. As expected, C synthesis was significantly elevated in the untreated npc1−/− mice (299 mg d−1kg−1) compared with the untreated npc1+/+ animals (157 mg d−1kg−1) (Fig. 2I), even though the whole-animals C pool in these pups was already greatly expanded (3,674 mg/kg) compared with the control animals (2,347 mg/kg) (Fig. 2D). In contrast, even though the pool of C in the liver cells was markedly expanded in the npc1−/− animals, synthesis was 12-fold higher (2629 mmol h−1 g−1). Although treatment of the npc1−/− pups with CYCLO had no significant effect on either of these parameters, the effects in the npc1−/− animals were very large. The markedly elevated rate of sterol synthesis was suppressed nearly to 0 (Fig. 2D), the concentration of C markedly decreased, the level of CE increased 14-fold (from 0.3 to 4.3 mg/g), and total sterol concentration in the liver significantly declined (Fig. 2A). Of note, although the synthesis of C was markedly suppressed, the synthesis of fatty acids was unchanged in CYCLO-treated (5.82 mmol h−1 g−1) vs. untreated (5.83 mmol h−1 g−1) npc1−/− pups. Although quantitatively less profound, similar changes were seen in the brain of the npc1−/− mice, where treatment with CYCLO increased the concentration of CE nearly 14-fold (from 0.3 to 4.3 mg/g), and total sterol concentration in the liver significantly declined (Fig. 2A). Furthermore, such changes were also seen in the remaining tissues of the carcass, which manifest increased in both the concentration of C (Fig. 2C) and rates of synthesis (Fig. 2F) in the untreated npc1−/− pups. Administration of CYCLO significantly lowered the mean concentration of sterol in these tissues and returned the rates of synthesis to those seen in the untreated npc1−/− animals.

Acute Effects of CYCLO Administration on Sterol Metabolism in Liver, Brain, and Whole Animal. Initial experiments examined the acute effects of CYCLO administered to 7-day-old mice and studied 24 h later. The 8-day-old npc1+/+ pups given only saline had a slightly elevated hepatic cholesterol ester (CE) concentration (0.86 mg/g), reflecting the increased intake of dietary C during suckling (60 mg d−1kg−1), so that the total sterol concentration (3.3 mg/g) was also marginally elevated (Fig. 2A). However, the 8-day-old npc1−/− pups given only saline already manifested a 5-fold increase in total hepatic sterol concentration (16.8 mg/g), nearly all of which was unesterified (16.5 mg/g). Because of the increased dietary sterol intake, hepatic synthesis in the npc1−/− pups was partially suppressed (216 mmol h−1 g−1) (Fig. 2D). In contrast, even though the pool of C in the liver cells was markedly expanded in the npc1−/− animals, synthesis was 12-fold higher (2629 mmol h−1 g−1). Although treatment of the npc1−/− pups with CYCLO had no significant effect on either of these parameters, the effects in the npc1−/− animals were very large. The markedly elevated rate of sterol synthesis was suppressed nearly to 0 (Fig. 2D), the concentration of C markedly decreased, the level of CE increased 14-fold (from 0.3 to 4.3 mg/g), and total sterol concentration in the liver significantly declined (Fig. 2A). Of note, although the synthesis of C was markedly suppressed, the synthesis of fatty acids was unchanged in CYCLO-treated (5.82 mmol h−1 g−1) vs. untreated (5.83 mmol h−1 g−1) npc1−/− pups. Although quantitatively less profound, similar changes were seen in the brain of the npc1−/− mice, where treatment with CYCLO increased the concentration of CE nearly 14-fold (from 0.3 to 4.3 mg/g), and total sterol concentration in the liver significantly declined (Fig. 2A). Furthermore, such changes were also seen in the remaining tissues of the carcass, which manifest increased in both the concentration of C (Fig. 2C) and rates of synthesis (Fig. 2F) in the untreated npc1−/− pups. Administration of CYCLO significantly lowered the mean concentration of sterol in these tissues and returned the rates of synthesis to those seen in the untreated npc1−/− animals.

When 14C-CYCLO was administered along with the dose of unlabeled compound and monitored, the molecule was cleared more slowly in the 7-day-old pups, such that after 6 and 24 h, respectively, 66% and 9% of the administered dose remained in the animals. The results were different in the 49-day-old mice, where only 8% and 3%, respectively, of the dose was found in the animals at these 2 times. From the dose of the compound administered, these data on whole-animal turnover, and rates of bulk-phase endocytosis (3), it could be calculated that the theoretical maximum amount of CYCLO taken up into the liver of the 7-day-old pups through bulk-phase endocytosis and delivered into the late E/L compartment during the 24-h interval would have equaled ~540 mg/kg (~14% of the administered dose). Based on these preliminary observations, all subsequent studies designed to elucidate the mechanisms involved in this marked prolongation of life were undertaken in mice given a single dose of CYCLO 4.5 (4,000 mg/kg) alone at 7 days of age.
Acute Effects of CYCLO Administration on Major Regulatory Mechanisms in Liver and Brain. If, in fact, CYCLO treatment had promoted such a sudden efflux of C into the cytosolic compartment, there should be major changes manifested in the 2 regulatory systems in this compartment, sterol regulatory element 2 (SREBP2) and liver X receptor (LXR), known to respond to variations in the size of the metabolically active sterol pool (17, 18). Because sterol O-acyltransferase 2 in the liver is constitutive, relative mRNA levels for this gene were the same in the 4 groups of pups (Fig. 3 A). In contrast, mRNA levels for SREBP2 and its target genes, 3-hydroxy-3-methylglutaryl coenzyme A (HMG CoA) synthase I (SYN), HMG CoA reductase (RED), and LDLR, were all significantly elevated in the untreated npcl−/− mice (Fig. 3 B−E). After CYCLO treatment, however, these mRNA levels were markedly suppressed, below even the levels seen in the npcl+/+ pups. In contrast, mRNA expression of the LXR target genes, ATP-binding cassette (ABC) A1, ABCG1, ABCG5, ABCG8, and cytochrome P450 7A1 (CYP7A1), was not elevated in the untreated npcl−/− mice (Fig. 3 F−J). After CYCLO treatment, however, the expression of ABCG1 and CYP7A1 became significantly elevated. Failure to observe a change in ABCA1 mRNA levels in liver is consistent with the report that the hepatic ABCA1 transcript isomorph is not under regulatory control of dietary C or LXR (19). Another characteristic feature of NPC disease of the liver is the presence of activated macrophages. This was reflected in elevated mRNA levels of a number of inflammatory factors, including CD11c, CD68, MIP-1α (chemokine ligand 3), and TLR4 but not TNF-α (Fig. 3 K−O). Of note, the mRNA level of TNF-α was elevated in older npcl−/− mice (20). Treatment with CYCLO also significantly reduced this overexpression. Brain showed similar changes 24 h after CYCLO administration. The relative mRNA level of SREBP2 and HMG CoA SYN was reduced (Fig. 3 P and Q), and that of the LXR target genes, ABCA1 and apoD, was significantly increased (Fig. 3 R and T). In addition, the elevated mRNA level of CD11c, reflecting activated glia in the brain, was restored to normal after CYCLO treatment (Fig. 3 S).

Long-Term Effects in the Adult Mouse of CYCLO Administration in Infancy. The next studies were designed to identify the long-term effects, if any, in 49-day-old adult mice that had been administered CYCLO at 7 days of age. Again, CYCLO administration to the npcl−/− mice had no effect on either C concentrations or synthesis rates in the liver, brain, and other organs (Fig. 4 A−C). However, there were marked residual effects in the npcl−/− animals. Six weeks after administration of CYCLO, when none of the compound was retained in the body, the concentration of C was still significantly reduced in the liver, kidney, spleen, and other organs. No reduction was seen in the brain, however, because most of the C in this organ is present in myelin, so that any changes that might have occurred in neurons are obscured. In addition, in nearly every organ, including the brain, C synthesis was increased (Fig. 4 E−G), presumably to offset the deficit of C in the metabolic pool, because sterol was again being sequestered in the late E/L compartment. As a consequence of these changes, 6 weeks after administration of the CYCLO, the whole-animal cholesterol pool was still reduced by >900 mg/kg even though synthesis was increased by 48 mg·d−1·kg−1 (Fig. 4 D and H).

The residual effects of this single dose of CYCLO on the clinical measures of disease were even more dramatic. The liver function tests, aspartate aminotransferase and alanine aminotransferase, were markedly improved (Fig. 4 I and J), and the level of neurodegeneration in the brain was significantly reduced. The npcl−/− mice had accumulations of vesicular storage material within the perikarya of neurons in multiple areas of the brain, most prominently in the neocortex, diencephalon, and ventral brainstem nuclei. In the cerebellum, there was marked loss of Purkinje cells, particularly in the anterior-superior cerebellar vermis, and this loss was accompanied by a proportional degree of Bergmann gliosis (Fig. 5 A and B). Storage material identical to that seen in the other perikarya was present in the cytoplasm of the remaining Purkinje cells. This cell death was also strikingly expressed in loss of calbindin immunoreactivity in the molecular layer (Fig. 5 D and E), reflecting loss of Purkinje cell dendrites, and by a marked increase in GFAP.
immunoreactivity (Fig. 5 G and H), indicating activation of glial cells in the areas of Purkinje cell loss. This neurodegeneration occurred in a band-like distribution similar to that described (21).

Although the single dose of CYCLO administered at 7 days of age did not alter the number of pyramidal cells present in the cerebral cortex of these 49-day-old animals (Fig. 4K), the number of surviving Purkinje cells in the cerebellum was more than doubled (Fig. 4L, 5C). This beneficial effect was also reflected in the substantial increase in calbindin immunoreactivity and the reduction in GFAP immunoreactivity seen in the cerebellum (Fig. 5 F and I), compared with untreated animals.

Finally, at 49 days of age, external sterol balance in the CYCLO-treated npc1<sup>−/−</sup> mice had returned to levels seen in the untreated animals (Fig. 4 M and N). The sum of the fecal neutral and acidic sterol outputs equaled ~190 mg d<sup>−1</sup>kg<sup>−1</sup> in both groups, which was significantly higher than the 120 mg d<sup>−1</sup>kg<sup>−1</sup> found in the untreated npc1<sup>−/−</sup> animals. Again, CYCLO administration had no effect on sterol balance in these control mice. Thus, apparently, the single dose of CYCLO had markedly lowered the whole-animal pool of sterol in these control mice.

To variable degrees, nearly all cells in the body take up lipoproteins carrying apoE or apoB<sub>100</sub>. The CE present in the hydrophobic core of these particles is processed in lysosomes by a lysosomal acid lipase (LAL) to C (22), which, in turn, is moved across the limiting membrane to the metabolically active pool of sterol in the cytosolic compartment by the concerted actions of NPC1 and NPC2. Mutations that inactivate LAL lead to accumulation of CE in the lysosomal compartment (Wolman disease) (23), whereas inactivation of NPC1 or NPC2 causes the sequestration of C (NPC disease). In the npc1<sup>−/−</sup> mouse, although this mutation leads to expansion of the C pool in the late E/L compartment (4), there is a perceived shortage of sterol in the rest of the cell. As a result, there is marked activation of the SREBP2 target genes with an increase in sterol synthesis, no stimulation of the LXR target genes, and almost no CE accumulation from the liver (59 mg d<sup>−1</sup>kg<sup>−1</sup>), whereas the remainder must have been excreted from the liver (59 mg d<sup>−1</sup>kg<sup>−1</sup>) either as C or, after conversion, to cholesterol (59 mg d<sup>−1</sup>kg<sup>−1</sup>), both of which are necessary for cell membrane synthesis.

**Discussion**

To variable degrees, nearly all cells in the body take up lipoproteins carrying apoE or apoB<sub>100</sub>. The CE present in the hydrophobic core of these particles is processed in lysosomes by a lysosomal acid lipase (LAL) to C (22), which, in turn, is moved across the limiting membrane to the metabolically active pool of sterol in the cytosolic compartment by the concerted actions of NPC1 and NPC2. Mutations that inactivate LAL lead to accumulation of CE in the lysosomal compartment (Wolman disease) (23), whereas inactivation of NPC1 or NPC2 causes the sequestration of C (NPC disease). In the npc1<sup>−/−</sup> mouse, although this mutation leads to expansion of the C pool in the late E/L compartment (4), there is a perceived shortage of sterol in the rest of the cell. As a result, there is marked activation of the SREBP2 target genes with an increase in sterol synthesis, no stimulation of the LXR target genes, and almost no CE accumulation from the liver (59 mg d<sup>−1</sup>kg<sup>−1</sup>), whereas the remainder must have been excreted from the liver (59 mg d<sup>−1</sup>kg<sup>−1</sup>) either as C or, after conversion, to cholesterol (59 mg d<sup>−1</sup>kg<sup>−1</sup>), both of which are necessary for cell membrane synthesis.
bile acid. In this manner, the hepatocytes attempted to adjust for the sudden influx of C into the metabolically active pool by immediately suppressing synthesis, sequestering much of the excess C as relatively inert CE, and excreting the remainder into bile. Similar, although less dramatic, changes were identified in the brain and remaining tissues of the body (Fig. 2). As a result, within only 24 h of administration, CYCLO had reduced the total C pool in the 8-day-old pups by nearly 500 mg/kg. Presumably, this increase in net excretion continued for several more days until the CYCLO was fully excreted from the body. CYCLO is a hydrophilic molecule containing a lipophilic pocket capable of solubilizing C and other hydrophobic molecules (24). It facilitates the movement of C between membranous structures by reducing the activation energy for desorption of the C molecule from ~20 kcal/mol to 7 kcal/mol (25). Depending on the concentration and molar ratio of CYCLO to C, a solution of this molecule can either extract sterol from cell membranes (CYCLO/C molar ratio of >60) or enrich the membrane with C (molar ratio <60) (26). In addition, at low concentrations (<1 mM), CYCLO can act catalytically, markedly enhancing the rate of molecular exchange of C between different hydrophobic compartments (27). Thus, one way in which CYCLO might have acted in the npc1<sup>−/−</sup> mice was to extract C from the plasma membranes of cells, facilitating its elimination from the body as the CYCLO was excreted by the kidneys. This is almost certainly not the case, however, in that there is no known pathway for C to move from the late E/L compartment directly to the plasma membrane in the npc1<sup>−/−</sup> cells. In addition, such a process would invariably lead to an increase in C synthesis and a reduction in the level of CE in cells. Importantly, no such effects were seen in the npc1<sup>−/−</sup> animals receiving CYCLO (Figs. 2 and 3), and in the npc1<sup>−/−</sup> mice, synthesis was actually suppressed, whereas the pool of CE was markedly expanded. A second possibility is that the CYCLO, reaching the late E/L compartment through bulk-phase endocytosis, altered the permeability of the limiting membrane in a nonspecific fashion, allowing C and other molecules to flow into the cytosolic compartment. This possibility also is unlikely, because any change in lysosomal permeability that released aspartic and serine proteases would likely lead to apoptosis and worsening of the disease seen in various organs (28). In the present studies, however, treatment with CYCLO actually decreased cell death and improved measures of tissue integrity (Figs. 4 and 5).

A third possibility is that CYCLO reaching the late E/L compartment through bulk-phase endocytosis either activated some, as...
yet, undescribed secondary C transporter or, more likely, acted in a catalytic fashion to promote C transfer, bypassing the defective function of the mutant NPC1 protein. Originally, it seemed reasonable that during lysosomal processing of CE, the sequence of events was for LAL to release C to the soluble NPC2, which, in turn, would then transfer it to NPC1 for translocation across the limiting membrane. Recent findings, however, have raised the possibility that the direction of C movement may be from LAL to NPC1, from NPC1 to NPC2, and from NPC2 to some as yet undescribed transporter located in the limiting membrane (29, 30). If this scenario is correct, CYCLO might act in the late E/L compartment by shuttling C between LAL and NPC2, thereby bypassing the defective NPC1. This would fully account for the observation that the flow of C out of the late E/L compartment into the metabolically active pool suddenly increased to 233 mg·d⁻¹·kg⁻¹, leading to massive expansion of the CE pool, suppression of the SREBP2 system, and activation of certain LXR target genes.

These studies establish that the single dose of CYCLO administered at 7 days of age transiently overcame the transport defect in the late E/L compartment, temporarily suppressing further synthesis of sterol and allowing a major portion of the sequestered pool to be metabolized and excreted from the body. This reduced the total body burden of C by nearly 500 mg/kg after 24 h and by 900 mg/kg after 6 weeks. Even this transient effect markedly reduced the activation and influx of macrophages into the liver and brain, significantly improved liver function and Purkinje cell survival, and, ultimately, led to increased lifespan. The fact that significant alterations in brain biochemistry and nerve cell survival occurred after these injections clearly implied that the reflection coefficient for CYCLO in the central nervous system, although presumably high, was not 1.0. Given these very favorable biochemical and clinical alterations following the single injection, the question arises as to whether repeated injections of CYCLO over time might completely prevent the increase in total body C burden and, essentially, prevent the organ dysfunction seen in NPC disease.

Further, it must be established whether the reflection coefficient for CYCLO in the brain does become 1.0 as the animal ages and, therefore, whether such continuous CYCLO administration must be carried out both systemically, to prevent the lung and liver disease, and into the central nervous system, to halt the neurodegeneration.

Materials and Methods

**Animals.** WT (npc1⁻/⁻) and homozygous mutant (npc1⁻/⁻) mice were generated from heterozygous (npc1⁺/⁻) animals with a pure BALB/c background (6, 15). Npc1⁻/⁻ mice were genotyped for age, except in those experiments using 7-day-old animals, where the pups were genotyped at 5 days of age. All animals were housed in plastic colony cages in rooms with alternating 12-h periods of dark and light and were studied in the fed state. For the experiments using 49-day-old mice, there were comparable numbers of males and females in every group. The gender of the mice studied at 8 days of age was not determined. The dark phase began at 24.00 h and lasted 12 h. All experimental protocols were approved by the Institutional Animal Care and Use Committee of the University of Texas Southwestern Medical School.

**Treatments and Diets.** All animals except the heterozygous breeding stock were fed ad libitum a cereal-based low-cholesterol (0.02% wt/wt) diet (no. 7001; Harlan Teklad) or a ground form of this same diet containing zeatinimbe (Schering-Plough Research Institute) (0.0125% wt/wt, providing ~20 mg·d⁻¹·kg⁻¹·bw) on weaning at 19 days of age. The breeding stock was maintained on another formulation containing 0.03% wt/wt cholesterol diet (no. 7002; Harlan Teklad). Mice were administered a single s.c. injection during the late dark phase at the scruff of the neck at 7 days of age of a 20% (wt/vol in saline) solution of CYCLO (6,000 mg/kg·bw) with either 5.6% of substitution (product 332607; Aldrich) or 4.5% of substitution (product H107; Sigma). In some experiments, Allo (P 8887; Sigma) was added to the CYCLO solutions at a concentration of 1.5 mg/ml (25 mg/kg·bw) (15, 16). Matching mice injected with saline only served as controls. All mice were studied either 24 or 42 days later at the end of the dark cycle, when the animals were either 8 days or 49 days old, respectively.

**CYCLO Pharmacokinetics.** Whole-body CYCLO clearance was measured in 7- and 49-day-old mice using ¹⁴C-CYCLO. Aliquots of the stock solution of ¹⁴C-CYCLO (1.0 mCi/ml) were diluted with a 20% (wt/vol) solution of nonradiolabeled CYCLO just before administration to the mice, which were subsequently killed at various time points up to 24 h. The proportion of the administered ¹⁴C-CYCLO dose that was retained by the body at each time point was determined by scintillation spectrometry after complete chemical digestion of the entire carcass. These data were used to calculate the proportion of the administered dose of ¹⁴C-CYCLO that had been cleared from the animal over each respective time interval.

Additional materials and methods are described in supporting information (SI) Materials and Methods and Table S1.
